### **ABSTRACT**

Vehicles produce sound signals with varying temporal and spectral properties under different working conditions. These sounds are indicative of the condition of the engine. Fault diagnosis is a significantly difficult task in geographically remote places where expertise is scarce. Automated fault diagnosis can assist riders to assess the health condition of their vehicles. This paper presents a method for fault detection and location in motorcycles based on the chain code of the pseudospectra and Mel-frequency cepstral coefficient (MFCC) features of acoustic signals. The work comprises two stages: fault detection and fault location. The fault detection stage uses the chain code of the pseudospectrum as a feature vector. If the motorcycle is identified as faulty, the MFCCs of the same sample are computed and used as features for fault location. Both stages employ dynamic time warping for the classification of faults. Five types of faults in motorcycles are considered in this work. Observed classification rates are over 90% for the fault detection stage and over 94% for the fault location stage. The work identifies other interesting applications in the development of acoustic fingerprints for fault diagnosis of machinery, tuning of musical instruments, medical diagnosis, etc.

**Keywords:** Motorcycle fault diagnosis; pseudospectral analysis; acoustic signal; DTW classifier.

### **INTRODUCTION**

Motorcycles are the favorite mode of transport in India. They account for the majority of the Indian automobile market with nearly 77% of the share of total vehicle sales. Two-wheelers registered a growth of 15.94% during April–August 2011. Unit sales of motorcycles are estimated to exceed 10 million by 2012–13 (IR, 2010). Vehicles produce different sound patterns under different working conditions when in motion. Service mechanics can diagnose faults based on the sounds produced by using the expertise acquired over many years. Vehicle classification and fault diagnosis based on acoustic signals adds further difficulty to analyzing sound patterns. The most influential factors include the non-stationary nature of the sound, and variations in speed, engine condition, road condition, and the surrounding environment. Some speech processing techniques such as the hidden Markov models are not suitable for these applications because of the lack of alphabet sounds.

The proposed work is divided into two stages: fault detection, and fault location. The terms location and localization are used interchangeably in this paper. In the fault

detection stage, the chain codes of the pseudospectrum of the sound signal are used as feature vectors. The extracted chain codes are used as input to dynamic time warping (DTW) techniques for classification. If a sound sample of a motorcycle is identified as faulty in the first stage, it is subjected to the fault location stage. The work employs Mel-frequency cepstral coefficient (MFCC) features for fault location, which are used for speech and speaker recognition. The need, applications, market scenario, and accident-prone Indian rural road conditions motivated this research. The work intends to alert riders to the possibility of accidents by indicating faults well in advance. It is also useful for service station experts in their preliminary analysis of faulty vehicles. The conducted literature survey is divided into two parts: engine fault diagnosis and gearbox fault diagnosis. 1D central contour moments and invariant contour moments of approximation coefficients of DWT have been used as inputs for the DTW classifier for detecting the condition of motorized two-wheelers based on acoustic signals (Anami, Pagi, & Magi, 2011; Tan & Wong, 2012). The entropy of db4 wavelet for feature extraction and a functional link neural network has been employed for fault diagnosis of the motorbike engine (Paulraj, Yaacob, & Mohd Zubir, 2009). A fault diagnosis system has been proposed for a scooter engine platform (Wu, Chang, Liao, Kuo, & Huang, 2009). The system uses continuous wavelet transform and artificial neural network techniques. The mechanisms of engine front noise generation and the corresponding countermeasures employed in the development of a diesel engine have been surveyed using a sound intensity method (JunHong & Bing, 2005). A de-noising method uses the Morlet wavelet for extracting the features of sound of vehicle engines with different types of failure.

Localized gear tooth defect recognition by Engin and Gulez (1999) used a wavelet-transform-based artificial neural network. An adaptive wavelet filter based on the Morlet wavelet has been presented for the detection of vibration signals of a gearbox (Lin & Zuo, 2003). RMS and power spectral density have been used for the fault diagnosis of a Massey Ferguson gearbox (Heidarbeigi, Ahmadi, Omid, & Tabatabaefar, 2009). A methodology for gearbox fault location detection used acoustic emission sensors for a split-torque gearbox and used wavelet transform techniques (He, Li, & Bechhoefer, 2010).

Some of the limitations of the reported works include:

- i) Computationally expensive methods and lack of robustness.
- ii) Lack of analysis for separability of the features.
- iii) Morlet-wavelet-based works are not fast because they have drawbacks such as an absence of a scaling function and not being orthogonal.
- iv) Dependency on knowledgebase poses a serious limitation when tested with new data.
- v) Lack of real-time applicability.
- vi) Lack of transparency due to larger feature sets.

From the comparative analysis of the literature, it is evident that a reasonable amount of research has been reported for a wide range of applications, covering fault classification, vehicle classification, and medical diagnosis. The reported works employ computationally expensive techniques that are not transferable to real-world environments and real-time applications. Comparison of our work with the reported works is difficult because of the differences in experimental conditions, recording

conditions, and databases. As there is no reported work on fault detection and location in motorcycles, based on their sound patterns, we have taken up this work.

## METHODOLOGY

The proposed methodology has two stages: fault detection and fault location. Fault detection determines whether the motorcycle is healthy or faulty, whereas the fault location stage identifies the exact source of the fault. Figure 1 depicts a block diagram of the proposed methodology.

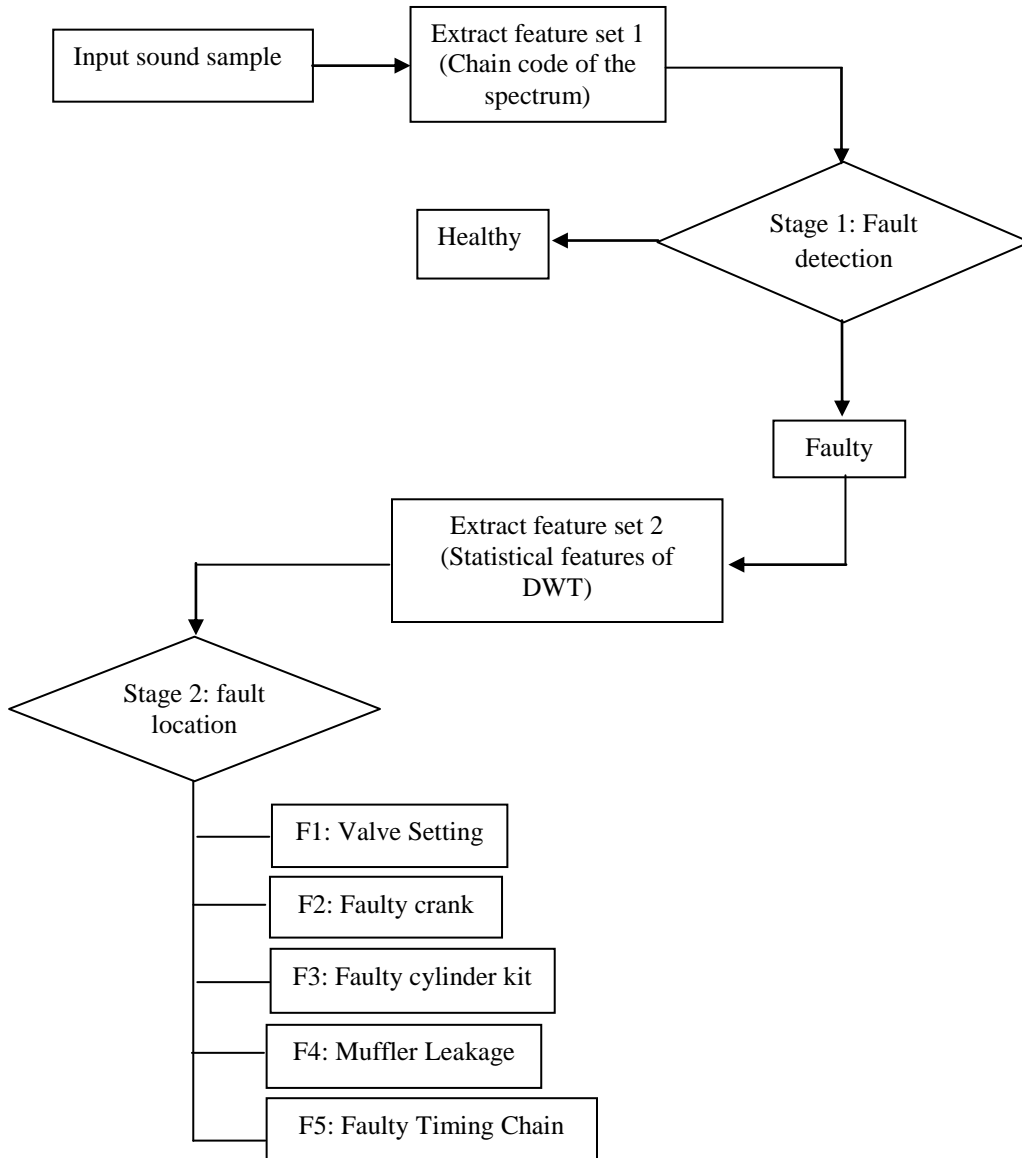

Figure 1. Block diagram of the proposed methodology.

The chain code of the estimated pseudospectrum of length 128 digits is employed as a feature vector. The extracted feature vector is used as input to the DTW classifier. The second stage employs MFCC features of the acoustic signals as input to the DTW classifier. The DTW classifier compares the test feature vector with the reference feature vectors. The smallest of the DTW distances indicates whether the sample is

healthy or faulty in the first stage, and it indicates the type of fault in the second stage. The reference feature vector for healthy motorcycles is computed as the mode of the chain codes of pseudospectra estimated from the healthy samples. The same procedure is followed for the computation of the reference feature vector for faulty motorcycles.

### **Stage 1: Fault detection based on chain codes of estimated pseudospectra and DTW**

Fault detection uses the chain code of the estimated pseudospectra as features computed over the recorded sound samples. The following subsections discuss the acquisition of sound samples, and feature extraction and classification, as applied to the fault detection stage.

#### **Acquisition of Sound samples**

A Sony ICD-PX720 digital voice recorder is used for recording the sound samples of motorcycles under idling conditions with no acceleration applied. The recording is performed with 44.1-kHz sampling frequency and 16-bit quantization. The service stations in which the recordings are obtained have additional disturbances from human speech, sounds of other vehicles being serviced, air-compressors, and other automobile repair tools. The recorder is held 500 mm from the end of the exhaust at the angle of 45° measured from the exhaust's centerline. The running of the engine and control of throttle are conducted by an expert mechanic. As the recording of samples is conducted in a real-world environment with surrounding disturbances, the method adopted is considered robust to extraneous noise.

Sound samples from healthy motorcycles are collected from those machines that are one-year old, have not passed 6000 km, and that have been serviced regularly. Sound samples of faulty motorcycles are collected from machines of varying age from one- to six-years old and that contain one of the aforementioned faults. 390 sound samples of healthy motorcycles and 390 sound samples of faulty motorcycles are used for the first stage, i.e., fault detection. Table 1 presents the details of the motorcycle sound samples considered in this work. The sound samples of motorcycles from the same manufacturer but from different models are considered for the second stage. A brief description of the faults considered in this work is given below:

**Valve setting:** Any deviation of between 5–10° in valve opening/closing causes a considerable rise in peak combustion chamber pressure, which leads to a change in engine sound.

**Crank fault:** This may occur owing to wear and tear of either oil ring, first ring or second ring.

**Muffler Leakage:** The reactive gases in the residual exhaust mixed with water vapor create an ideal environment for corrosion reactions. This results in minute holes in the muffler and changes the firing sound of the engine.

**Silencer leakage:** Silencer leakage is caused either by a hole inside the silencer filter pipe or by a damaged gasket.

**Timing Chain:** The main function of the timing chain is to operate the valves. A loose chain vibrates and results in a change of sound.

Table 1. Details of the motorcycles considered.

Sl. No	Model	Kilomet ers run	Age	Condition	Recording duration	No. of samples
1.	HH Spl +	529	2 M	Healthy	48 s	35

**Segmentation**

The acquired sound samples are segmented into samples, each of one-second duration, for uniformity in processing. The first segment is extracted beginning from the local maxima in the first 50-ms span. The subsequent segment begins at the local maxima of the next 50-ms duration from the end of the previous segment.

**Feature Extraction**

The slopes of the pseudospectral spans are employed as features. The estimated pseudospectral vector is divided into eight equal spans. The slope of each segment is computed to form a feature vector.

*Pseudospectrum Estimation*

The *pmusic* function of MATLAB is employed for pseudospectral estimation of the sound signals. The pseudospectrum is calculated by using estimates of the eigenvectors of a correlation matrix associated with the input data  $x$ .  $[S, w] = pmusic(x, p)$  implements the MUSIC (Multiple Signal Classification) algorithm and returns  $S$ , the pseudospectrum estimate of the input signal  $x$ .  $p$  is the signal subspace dimension and  $w$  is a vector of normalized frequencies (in rad/sample) at which the pseudospectrum is evaluated. The MUSIC estimate is given by Eq. (1).

$$P_{music}(f) = \frac{1}{e^H(f) \left( \sum_{k=p+1}^N v_k v_k^H \right) e(f)} = \frac{1}{\sum_{k=p+1}^N |v_k^H e(f)|^2} \tag{1}$$

where  $N$  is the dimension of the eigenvectors and  $v_k$  is the  $k^{th}$  eigenvector of the correlation matrix of the input signal. The integer  $p$  is the dimension of the signal subspace, such that the eigenvectors  $v_k$  used in the sum correspond to the smallest eigenvalues and also span the noise subspace. The vector  $e(f)$  consists of complex exponentials, such that the inner product  $v_k^H e(f)$  amounts to a Fourier transform. Eq. (2) shows how the summation is weighted by the eigenvalues of the correlation matrix, as in the eigenvector method.

$$P_{ev}(f) = \frac{1}{\left( \sum_{k=p+1}^N |v_k^H e(f)|^2 \right) / \lambda_k} \tag{2}$$

Figure 2. Logarithmic plot of pseudospectral estimates of faults.

The function relies on the singular value decomposition (SVD) matrix decomposition in the signal case, and it uses the *eig* function for analyzing the correlation matrix. Logarithmic plots are used to analyze the separability exhibited by the pseudospectra for different faults considered in this study. Figure 2 shows the

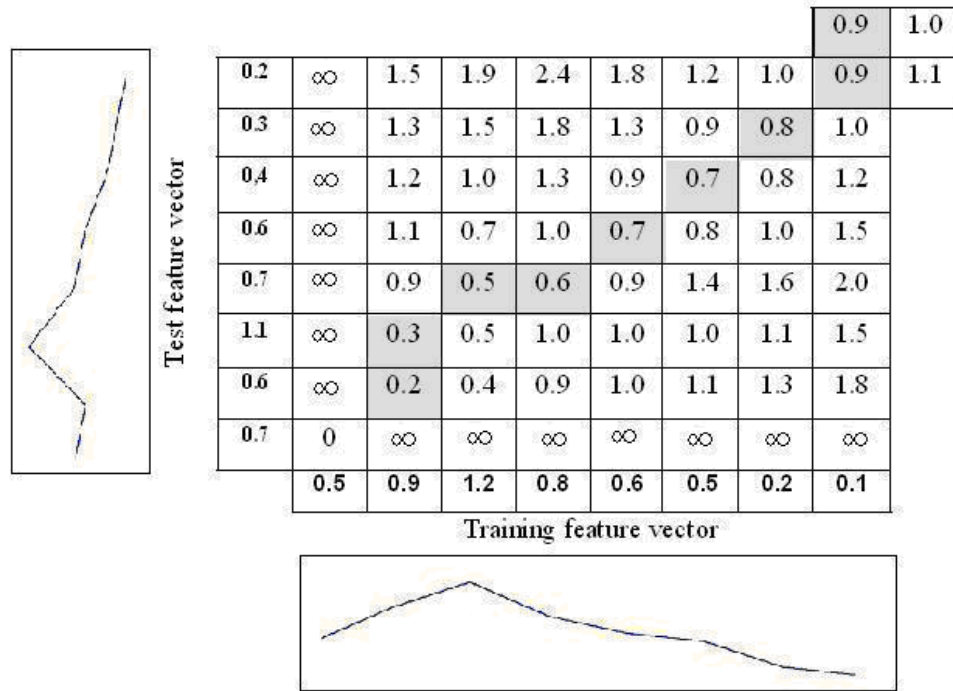

Figure 3. Illustration of working of DTW algorithm.

### Stage 2: Fault Location using MFCC Features

MFCCs are derived from a cepstral representation of the sound signal. The Mel-scale approximates the human auditory system’s response more closely than the linearly spaced frequency bands used in the normal cepstrum. The frequency bands are equally spaced on the Mel-scale. The MFCCs are computed first by taking the Fourier transform of a signal. Then, the powers of the spectrum are mapped onto the Mel scale using triangular overlapping windows. The logs of the powers at each of the Mel-frequencies are taken. A discrete cosine transform of the list of Mel log powers is performed. Finally, the amplitudes of the resulting spectrum, taken as MFCCs, are used as features in speech recognition, speaker recognition systems, and music information retrieval applications, such as genre classification, audio similarity measures, etc. MFCC values are noise sensitive for additive noise and hence, are not robust. MFCC features may not be optimal for vehicle fault diagnosis because the filter bank spreads out the fine details of the spectral patterns. Sometimes these details contribute significantly to the success of classification.

The motorcycle sound samples classified as faulty in the first stage are used as input for the fault location stage. The eight MFCCs are computed on a signal of one-second duration and used as features for fault localization. The reference feature vectors for this stage are computed as the mean of the feature vectors of respective fault types. The DTW algorithm compares the test feature vectors with the reference features of the five fault types.

## RESULTS AND DISCUSSION

Disjoint sample sets are used for training and testing. The sample set includes 390 samples of healthy motorcycles and 390 samples of faulty motorcycles. If  $n$  is the number of samples used for training, then  $(390-n)$  is the number of samples used for testing. For the first stage, the samples from healthy motorcycles of different brands and faulty motorcycles of the Hero Honda brand are considered. The following criterion is used for classification.

```

If ((EucDist(Test, meanDTW(H) < EucDist(Test, meanDTW(F))
    Class = Healthy;
else
    Class = Faulty;
    
```

where EucDist(x,y) – Euclidean distance of the vector x with vector y,  
 Test – Test vector,  
 meanDTW(H) – Mean of the DTW distances of healthy samples, i.e., reference vector for healthy samples;  
 meanDTW(F) - Mean of the DTW distances of faulty samples, i.e., reference vector for faulty samples;  
 Class – Health condition of the motorcycle.

The results of the first stage are shown in Figure 4.

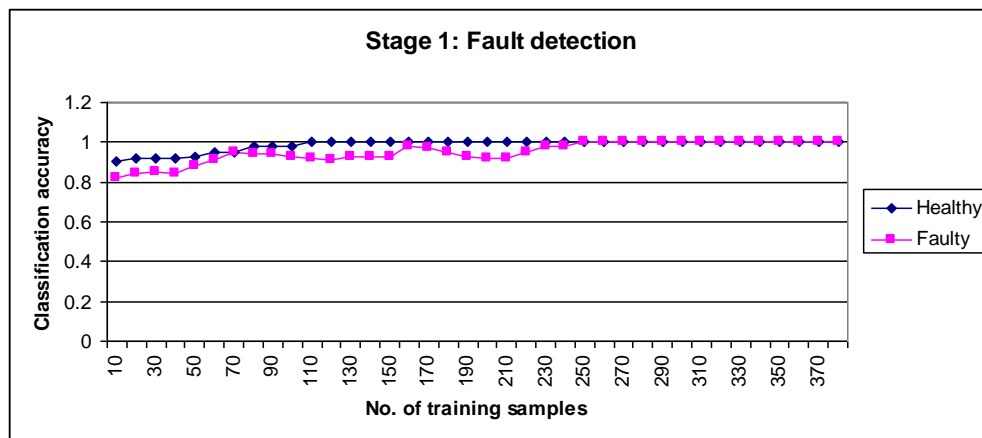

Figure 4. Performance of the classifier for fault detection.

Table 2 shows the confusion matrix for the fault location stage. Table 3 summarizes the classification performances for different fault types, which shows that the classification accuracy is 0.8108 for fault type 3. Classification accuracy of 1.0000 is attained in the case of fault type 2. Out of 390 samples considered, 369 samples are correctly classified, yielding the overall classification accuracy of 0.9453. From Table 3, it can be inferred that the MFCC features, which are employed for speech recognition, can be applied for non-speech applications. The signals are not preprocessed for denoising, but the results are quite satisfactory and hence, the features and the methodology are found to be robust. DTW is suitable for classifying samples with a limited database. Use of dynamic programming ensures a polynomial complexity

of  $O(n^2v)$ , where  $n$  is length of the sequence and  $v$  is the number of samples in the training set. However, the  $O(n^2v)$  complexity is not satisfactory for a large database. DTW is appropriate for applications that need simple word recognition, reliability tests in manufacturing units, initial servicing activities in service stations, speech recognition in telephones, etc.

Table 2. Confusion matrix for fault location.

	F1	F2	F3	F4	F5
F1	49	0	0	0	3
F2	0	36	0	0	0
F3	0	0	30	0	7
F4	0	0	0	54	0
F5	1	7	0	0	210

Table 3. Classification performance for different faults.

Fault type	Fault	Total No. of samples	No. of samples correctly classified	No. of samples misclassified	No. of samples not classified	Classification accuracy
F1	Valve setting	52	49	3	0	0.9455
F2	Faulty crank	36	36	0	0	1.0000
F3	Muffler leakage	37	30	7	0	0.8108

F5	Timing chain	210	200	8	2	0.9524
	Total	390	369	18	3	0.9461

### CONCLUSION

A two-stage methodology for the fault diagnosis of motorcycles, based on sound patterns, is presented in this paper. The fault detection stage uses the chain codes of the estimated pseudospectra of the sound samples. Fault location is attempted by using MFCC features of the sound samples. Both stages employ the DTW classifier. The results for fault location differ for each type of fault. This can be attributed to the similarity of the sounds of the faults belonging to the same subsystem. The overall classification rate for fault location is around 94%. This work leaves future scope for fault location in different subsystems of motorcycles and for the detection of multiple faults. It finds applications in acoustic-signal-based machine fault detection and location, cardiac signal analysis, musical instrument tuning, and spoken-word analysis, etc.
