ABSTRACT

The discharge of dye-containing effluents into the aquatic environment represents a source of aesthetic pollution with associated negative effects. Photocatalytic degradation has been identified as a suitable means of treating these effluents. In this study, the potential of a locally sourced material, periwinkle shell ash (PSA), has been explored as an effective photocatalyst for the photocatalytic decolourisation of tartrazine in aqueous solution. The efficiency of the photocatalyst was evaluated by investigating the effects of operational variables such as irradiation time, initial dye concentration and catalyst loading on the extent of decolourisation. The results show that the optimum levels of the variables were 50 minutes, 30 mg/L and 5 g/L for irradiation time, initial dye concentration and catalyst loading respectively. The pseudo first order and the Langmuir-Hinshelwood kinetic models were able to sufficiently describe the kinetics of the process. The diffusion mechanism was described by the intra-particle diffusion model while the adsorption equilibrium was described by the Langmuir isotherm equation. The results obtained indicate that PSA can be used as an effective photocatalyst for the removal of tartrazine from aqueous solution.

Keywords: Periwinkle shell ash; tartrazine; kinetics; isotherm; equilibrium.

INTRODUCTION

Water pollution due to the discharge of coloured effluents from textile dye manufacturing and textile dye mills is one of the major environmental concerns in the world today [1]. It has been reported that between 1 and 20% of the dye is lost during the dyeing process and it is subsequently released in wastewater [2]. The release of these coloured wastewaters poses serious aesthetic and ecological problems such as eutrophication to the aquatic ecosystems [3]. Azo dyes are considered to be the largest group among the established classes of synthetic dyes and an important example is tartrazine. Tartrazine is a useful colorant widely employed in food products, drugs, cosmetics etc. Nevertheless, the toxic and harmful effects of tartrazine have been established by numerous studies [4-7]. Hence, these types of dyes have been classified as potentially carcinogenic and mutagenic by the US National Institution for Occupational Safety and Health [8]. Their chemical structures are characterised by
highly substituted aromatic rings joined by one or more azo groups [9]. These substituted ring structures make the dye molecules recalcitrant and not readily amenable to degradation by conventional wastewater treatment methods [10].

Different physical, chemical and biological methods have been applied for the treatment of dye-containing effluents. Physical methods are not effective, they do not degrade the dye and the dyes are merely transferred to another phase, thereby introducing the need for further treatment steps [11]. Biological methods appear to be effective and economical. However, this treatment does not lead to the mineralisation of the dyes as they are only adsorbed on the sludge [3]. Heterogeneous photocatalytic degradation facilitated by semiconductor catalysts has been identified as a promising technique for the removal of most dyes from liquid effluents [10, 12]. The photocatalytic reaction takes place when the semiconductor particle absorbs a photon of light which is more energetic than its band gap, leading to the excitation of the electron from the valence band to the conduction band. A hole–electron pair is formed in the process and this initiates the oxidation of the dye [13]. The important advantage of this method is that it often results in complete mineralisation and degradation of most pollutants that are not amenable to other treatment processes [14]. Furthermore, it is cheaper than most processes and it can be carried out under ambient conditions [1]. Several studies have been carried out on photocatalytic degradation of dyes, mainly with TiO\(_2\)/UV or ZnO/UV systems, and these studies have established the factors that influence the rate of the photocatalytic reaction [15-20]. However, TiO\(_2\) has an important shortcoming in that it absorbs only a limited amount of photons in the UV region. Hence it requires a high power UV excitation source to function effectively [21]. Some researchers have reported the preparation of photocatalysts from waste materials [22-25]. However, very little work has been reported on the preparation of photocatalysts from periwinkle shells [12, 26, 27]. Hence the focus of this work is to evaluate the potential application of periwinkle shell ash as a photocatalyst for the photocatalytic decolourisation of tartrazine in aqueous solutions. The effects of operational variables such as irradiation time, initial dye concentration and catalyst loading on the decolourisation process were investigated. The photocatalytic decolourisation of tartrazine was further evaluated by carrying out kinetic (pseudo first order, pseudo second order, intra-particle diffusion and Langmuir-Hinshelwood models) and isotherm studies (Langmuir and Freundlich isotherms).

**MATERIALS AND METHODS**

**Preparation and Characterisation of Periwinkle Shell Ash**

Periwinkle shells were sourced locally from Benin City in Edo State of Nigeria. The shells were washed and dried in an oven at 110 °C to constant mass, followed by crushing and calcination at 600 °C in a muffle furnace and subsequent sieving to obtain fine particles (< 350 μm) of periwinkle shell ash (PSA). The prepared PSA was characterised by determining the composition using X-ray fluorescence (XRF) analysis. X-ray diffraction (XRD) was used to determine the ultimate elemental composition of the PSA using a Philips X-ray diffractometer [12, 28]. The functional groups on the PSA surface were determined by Fourier transform infrared spectrometry (FTIR) using a Perkin Elmer spectrum 100 FT–IR spectrometer in the frequency range 4000 to 400 cm\(^{-1}\), operating in ATR (attenuated total reflectance) mode. The surface structure and
other properties of the PSA were evaluated by the nitrogen adsorption method at -196 °C. The surface area of the PSA was determined using the standard BET equation.

**Dye**

All reagents and chemicals used in this study were of analytical grade and were used without further purification. Tartrazine dye with molecular formula $C_{16}H_9N_4Na_3O_9S_2$ and molecular weight 534.36 g/mol was obtained from Stanvac Laboratories in Benin City, Edo State, Nigeria. The molecular structure of the dye is shown in Figure 1.

![Figure 1. Chemical structure of tartrazine “trisodium 1-(4-sulfonatophenyl)-4-(4-sulfonatophenylazo)-5-pyrazolone-3-carboxylate” [8].](image)

**Photoreactor**

The experimental set-up has been described previously [12]. The reactor was irradiated by four UV lamps emitting at 254 nm (40 W, Philips TUV G6T5). The intensity of the light emitted by the lamps was measured as 1.65 mW/cm$^2$ using a Lux-UV-IR meter (Leybold Co.).

**Photocatalytic Degradation Studies**

The dye solution was prepared in appropriate concentrations using deionised water. The photocatalytic decolourisation studies were conducted using 4000 mL of dye solution and a predetermined quantity of photocatalyst. With the UV lamps still off, air was bubbled at a predetermined flowrate through the dye solution in the holding tank. The lamps were subsequently turned on and the pump was started to convey the dye-catalyst suspension into the reactor. Samples of 25 mL aliquots were withdrawn at regular intervals and were immediately centrifuged at 8000 rpm for 10 min to remove suspended catalyst particles. The progress of the photocatalytic decolourisation process was monitored by measuring the absorbance of the samples with a UV–Visible spectrophotometer (Shimadzu UV 2101 PC) at a wavelength of 520 nm. A calibration curve based on Beer–Lambert’s law was established by relating the absorbance to the concentration. The effect of irradiation time, initial dye concentration and photocatalyst loading on the decolourisation efficiency was then investigated. The percentage photocatalytic decolourisation of tartrazine dye was calculated using Eq. (1).

$$\text{Decolourisation efficiency} = \frac{C_o - C_t}{C_o} \times 100$$

The amounts of tartrazine adsorbed at time $t$, ($q_t$) and at equilibrium ($q_e$) were calculated using Eqs. (2)–(3).

$$q_t = \frac{V_s(C_o - C_t)}{W}$$

$$q_e = \frac{V_sC_o}{W}$$
\[ q_e = \frac{V_s(C_o - C_f)}{W} \]  

(3)

where \( C_o, C_e \) and \( C_f \) are the initial, equilibrium and instantaneous concentrations of tartrazine respectively. \( V_s \) is the volume of the aqueous solution and \( W \) is the amount of catalyst.

RESULTS AND DISCUSSION

Characterisation of Photocatalyst

The results of the chemical composition analysis of the PSA have been previously reported [12, 26]. The XRF results indicated that the major constituents of the PSA were calcium oxide (CaO), silica (SiO\(_2\)) and aluminium oxide (Al\(_2\)O\(_3\)), which respectively accounted for 41.3, 33.2 and 9.2\% of the weight of PSA analysed. XRD results indicated that the major elements in PSA were iron (Fe) and zinc (Zn), which respectively accounted for 19.2 and 16.5\% of the weight of PSA analysed. Other oxides and elements were also present but in small proportions. Navaladian et al. [29] reported that transition metals and their oxides are known to exhibit catalytic properties, thus supporting the choice of PSA for this study. Similar observations have been reported by other researchers [18, 30]. The surface area, bulk density, and porosity of the PSA were similar to those reported in the literature [31, 32]. FTIR results revealed peaks of 3626.59 cm\(^{-1}\), 1797.58 cm\(^{-1}\), 1561.43 cm\(^{-1}\) and 1374.34 cm\(^{-1}\) in the infrared spectrum of periwinkle shell ash, corresponding to O–H, C= O, C= C and C–H bonds respectively. Absorption bands in the range of 2700 to 1430 cm\(^{-1}\) and 900 to 1380 cm\(^{-1}\) indicate the presence of phenyl groups and the stretching of the C–O bond in carboxylic groups present in the PSA [33]. These FTIR bands represent functional groups that possess strong bonds which can be protonated in slightly acidic conditions to be potential adsorption sites for organic molecules [34].

Effect of Irradiation Time

Figure 2 shows the effect of irradiation time on the photocatalytic decolourisation of tartrazine by PSA. The decolourisation efficiency showed a steady and progressive increase with increase in irradiation time, to attain a maximum value of about 81\% at an irradiation time of 50 minutes. Increasing the irradiation time beyond 50 minutes did not have any impact on the decolourisation process. The initial increase in the decolourisation efficiency could be attributed to the abundance of active sites on the surface of the photocatalyst, which favoured the photocatalytic reaction [35]. As the reaction proceeds further, these active sites are then occupied by several layers of dye molecules, such that the rate of the decolourisation reaction slows down. Furthermore, the insignificant change in the decolourisation efficiency observed beyond 50 minutes of irradiation time could also indicate that the system had attained a state of equilibrium, which means that the catalyst had become saturated and could no longer adsorb any more dye molecules [8]. Equilibrium times in the range of 90 to 120 minutes were reported by Chakrabarti and Dutta [36] under varying conditions of photocatalytic degradation of model textile dyes in wastewater using ZnO as photocatalyst. Akyol et al. [37] reported lower equilibrium times of 25 and 35 minutes respectively for the photocatalytic decolourisation of Remazol Red RR in aqueous systems using ZnO and
Preparation and investigation of the photocatalytic properties of periwinkle shell ash for tartrazine decolourisation

TiO$_2$ as photocatalysts. These results show that the photocatalytic decolourisation of dyes is a fast kinetic process.

Effect of Initial Dye Concentration

The initial concentration of the dye solution influenced the decolourisation process as shown in Figure 3. The decolourisation efficiency initially increased from about 8% to about 83% when the initial dye concentration was increased from 10 to 30 mg/L. Increasing the concentration of dye beyond 30 mg/L resulted in a decrease in the decolourisation efficiency. Konstantinou and Albanis [38] noted that the rate of dye degradation generally increases with the increase in dye concentration up to a certain level beyond which any further increase in dye concentration does not positively affect the degradation process. Similar observations have been reported by Sakthivel et al. [18]. The rate of the degradation reaction is dependent on the rate of formation of the hydroxyl radicals as well as the probability of the radicals reacting with the dye molecules. As the concentration of dye is increased, there will be more of the dye molecules in the solution and this will increase the probability of the radicals reacting with the dye molecules, consequently resulting in an enhancement of the rate of the degradation of the dye [38]. However, as the concentration of dye is increased beyond the optimum point, the decolourisation efficiency decreased because of the decrease in the formation of hydroxyl radicals on the surface of the catalyst. The reason for this could be that the active sites on the catalyst surface are occupied by layers of dye molecules [39, 40]. Furthermore, at high concentrations of dye, a significant amount of the UV radiation could be absorbed by the dye molecules rather than the PSA particles and this reduces the efficiency of the decolourisation process because of the reduction in the rate of formation of the oxidising radicals [41].
Figure 3. Effect of initial dye concentration on the hotocatalytic decolourisation of tartrazine (PSA loading, 5 g/L; temperature, 25 °C).

**Effect of Catalyst Loading**

Figure 4 shows the effect of PSA loading on the decolourisation efficiency. With increase in PSA loading from 1 to 5 g/L, the decolourisation efficiency increased from about 19 to 85%. Further increase in PSA loading did not have any positive impact on the decolourisation process. The initial increase in decolourisation efficiency observed might be rationalised in terms of the availability of active sites on the PSA surface. The availability of active sites increases with increase in catalyst loading, and hence the rate of decolourisation is enhanced [15].

Inasmuch as elevated levels of catalyst loading increase the availability of active sites on the catalyst surface, they also lead to a reduction in the light penetration and consequently a reduction in the photoactivated volume of the suspension. This explains
the decrease in decolourisation efficiency observed beyond a catalyst loading of 5 g/L. Some researchers have suggested that at high catalyst loading, agglomeration and sedimentation of the catalyst particles could occur, making a fraction of the catalyst surface unavailable for photon and dye absorption [42]. According to Suri et al. [43], the optimum catalyst dosage could be dependent on the initial solute concentration. They further suggested that it might not be advisable to use higher catalyst loadings as a result of possible aggregation and reduced irradiation field.

Kinetics of Photodegradation

For engineering purposes, it is important to determine a rate equation that fits the experimental data. Since adsorption is considered critical in the heterogeneous photocatalytic degradation process, the kinetics of the photodegradation process was studied using four kinetic models, namely pseudo first order, pseudo second order, intra-particle diffusion and Langmuir-Hinshelwood kinetic models. These models are elucidated in the following sections.

Pseudo First Order Model

The pseudo first order kinetic model is expressed in its integrated linear form as follows [44]:

\[ \ln(q_e - q_t) = \ln q_e - k_1 t \]  

where \( q_e \) and \( q_t \) (mg/g) are adsorption capacity at equilibrium and at time \( t \) respectively. \( k_1 \) is the rate constant of pseudo first order adsorption (1/min). The values of \( \ln(q_e - q_t) \) were plotted against \( t \). The plot of \( \ln(q_e - q_t) \) against \( t \) resulted in a linear relationship from which the values of \( k_1 \) and \( q_e \) were determined as shown in Figure 5. The values of the constants are given in Table 1. The linear relationship observed in Figure 5 suggests that the pseudo first order model was applicable to the process.

**Pseudo Second Order Model**

The pseudo second order kinetic model is expressed in its integrated linear form as follows [45]:

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{1}{q_e}$$

(5)

$k_2$ is the rate constant of the pseudo second order process (g/mg.min). The plot of $(t/q_t)$ versus $t$ as shown in Figure 6 was used to calculate the values of the model parameters. The kinetic constants calculated from the plot at different initial dye concentrations are shown in Table 1. It is very obvious from Figure 6 that the pseudo second order model was not able to represent the kinetics of the degradation process, as seen in the very low $R^2$ values (Table 1).

![Figure 6. Pseudo second order model results for tartrazine photodegradation by PSA (PSA loading, 5 g/L; temperature, 25 °C).](image)

**Intra-Particle Diffusion Model**

The diffusion mechanism of the process was modelled using the intra-particle diffusion model as follows [46]:

$$q_t = K_P t^{1/2} + C$$

(6)
$K_p$ is the intra-particle diffusion rate constant (mg/g.min$^{1/2}$) and $C$ is a measure of the boundary layer effect. The values of the intra-particle diffusion model parameters at different initial dye concentrations are presented in Table 1. The plot of $q_t$ versus $t^{1/2}$ from which the parameters were calculated is shown in Figure 7. The plot indicates the existence (although not significant) of some boundary layer effect and further showed that intra-particle diffusion was not the only rate-limiting step. The high $R^2$ values obtained for the kinetic parameters estimated within the concentration range investigated showed that the intra-particle diffusion model was able to describe the diffusion mechanism of the process.

**Langmuir-Hinshelwood Model**

The Langmuir–Hinshelwood kinetic model developed by Turchi and Ollis [47] can be expressed as follows:

$$r_o = \frac{dc}{dt} = \frac{k_rKC_{eq}}{1 + KC_{eq}}$$  \hspace{1cm} (7)

$r_o$ is the initial rate of reaction in mg/L.min, $k_r$ is the rate constant for photocatalysis in mg/L.min, $K$ is the rate constant for adsorption in L/mg, $C_{eq}$ is the concentration of bulk solution in mg/L at adsorption equilibrium, $c$ is the concentration of bulk solution at any time $t$. Eq. (7) may be expressed in its linearised form as follows:

$$\frac{1}{r_o} = \frac{1}{k_rK C_{eq}} + \frac{1}{k_r}$$  \hspace{1cm} (8)

Values of $1/r_o$ were plotted against $1/C_{eq}$ for the dye as shown in Figure 8 and the values of the calculated constants are presented in Table 1.

![Figure 7. Intra-particle diffusion model results for tartrazine photodegradation by PSA (PSA loading, 5 g/L; temperature, 25 °C).](image-url)
Adsorption Isotherm Studies

The Langmuir and Freundlich adsorption isotherm models were used to analyse the equilibrium data for the photocatalytic degradation of tartrazine dye.

Langmuir Isotherm

The Langmuir isotherm model, which assumes monolayer adsorption of the adsorbate, can be expressed in its linear form as follows [48]:

\[
\frac{C_e}{q_e} = \frac{1}{q_o} + \frac{1}{K_L q_o}
\]

\[q_o\] is the maximum sorption capacity (mg/g) of the adsorbent while \(K_L\) is the sorption constant (L/mg). A linear plot of \(C_e/q_e\) against \(C_e\) as shown in Figure 9 was used to calculate the values of \(q_o\) and \(K_L\), which are presented in Table 2 alongside the correlation coefficient \(R^2\) value.

<table>
<thead>
<tr>

The separation factor \((R_L)\) can be used to determine whether or not the adsorption process will be favourable [50]. The parameter predicts that the type of isotherm could be irreversible \((R_L=0)\), favourable \((0<R_L<1)\) or unfavourable \((R_L > 1)\).

\[
R_L = \frac{1}{(1 + K_L C_o)}
\]

\(C_o\) is the initial concentration of tartrazine.

For this study, the values of $R_L$ given in Table 3 are between zero and one, indicating that the adsorption was favourable.

**Freundlich Isotherm**

The Freundlich equation is expressed as follows:

$$q_e = K_f (C_e)^{1/n}$$  \[51\]

Eq. [51] can be expressed in its linearised form as follows:

$$\ln q_e = \ln K_f + 1/n \ln C_e$$  \[52\]

$K_f$ and $n$ are the Freundlich constants related to the adsorption capacity and adsorption intensity respectively. A linear plot of $\ln q_e$ against $\ln C_e$ as shown in Figure 10 was employed to calculate the values of the constants. The values of these parameters as well as the correlation coefficient ($R^2$) of the Freundlich equation are given in Table 2. The values of $n$ between 1 and 10 typically indicate beneficial and favourable adsorption. Chakrabarti and Dutta [36] reported $K_f$ and $n$ values of 0.431 and 1.343 for the photocatalytic degradation of Methylene Blue in wastewater using ZnO as semiconductor catalyst. Agarry and Aremu [53] suggested that the difference between the values could be a result of differences in the range of concentration, type of material used, pH, temperature and properties of the adsorbent. The high values of the
correlation coefficients obtained for the Langmuir isotherm as shown in Table 2 indicate that the data conformed well with the Langmuir isotherm equation.

Figure 10. Freundlich isotherm model results for tartrazine photodegradation by PSA (PSA loading, 5 g/L; temperature, 25 °C).

CONCLUSIONS

Photocatalytic decolourisation of tartrazine was carried out in a continuous flow reactor using periwinkle shell ash as photocatalyst. The decolourisation process was affected by factors such as irradiation time, initial dye concentration and PSA loading dosage. For the conditions considered in this study, the optimum values obtained are as follows: irradiation time, 50 minutes; initial dye concentration, 30 mg/L and PSA loading, 5 g/L. The kinetics of the photodegradation of tartrazine was well described by the pseudo first order and the Langmuir-Hinshelwood kinetic models, with high correlation coefficient values ($R^2>0.9$). The diffusion mechanism and adsorption equilibrium were well described by the intra-particle diffusion model and the Langmuir isotherm equation respectively. PSA has proven to be a suitable alternative to commercially available photocatalysts like TiO$_2$ and ZnO.
